In a multimode photonic-crystal waveguide, we observe strong enhancement of the photoluminescence of embedded quantum dots at the edges of the so-called mini-stopband that were opened by Bragg diffraction between two guided modes. Taking into account light collection, we relate this observation to the singular photon density of states that is characteristic of a one-dimensional photon system. Furthermore, we quantify by how much the radiation losses smooth the divergence. For the first time to our knowledge, a clear account of the control of spontaneous emission in a one-dimensional system is thus demonstrated. © 2005 Optical Society of America

Periodic photonic structures exhibit interesting effects, such as enhanced gain^{1–3} anomalous group velocity and dispersion,^{1,4} at the photonic-band edges. Notably, the control of the spontaneous emission of emitters inside these periodic structures has been widely investigated.^{5–9}

One-dimensional (1D) photonic wires are of particular interest, as evidenced by Kleppner¹⁰ in 1981: A divergence of the photon density of states (DOS) occurs when the group velocity vanishes, either at mode cutoff frequency in typical wires or at band edge singularities in periodically structured wires.

Although 1D systems have been less investigated than their zero-dimensional counterparts,¹¹ in-plane studies of such photonic crystal waveguides have already shown the ability to lase at the band edge frequency.¹² An out-of-plane experiment also exhibited an enhancement of the spontaneous emission power at such a band edge.¹³ In this Letter we investigate the change in the power spectrum of spontaneous emission of quantum dots embedded inside a GaAs-based two-dimensional photonic crystal waveguide at a mini-stopband edge singularity. Peaks on the side of this mode gap are observed in a pure spontaneous emission regime; although they are reminiscent of below-threshold side modes in common distributed feedback laser diodes,¹⁴ no gain at all is involved here. Moreover, the excitation spot is very small, as it is diffraction limited. We relate these peaks to the calculated 1D photon density of states,

taking into account our collection geometry. This is what we believe is the first evidence of a photonic crystal based DOS divergence in a genuinely 1D system, with few discrete transverse modes.

The photonic crystal waveguides are carved in a triangular two-dimensional array of airholes defined by *e*-beam lithography and deep etching in a GaAs laserlike heterostructure, fully similar to those reported earlier,^{15,16} where *a* is the period of the triangular array, which contains three InAs quantum-dot

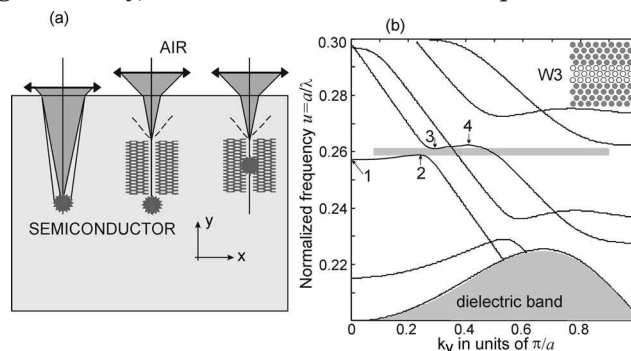

Fig. 1. (a) Internal light source and cleaved edge collection: left to right, reference, measurement of waveguide transmission, measurement of emission from inside the photonic crystal waveguide. (b) Dispersion relation of the W3 waveguide (inset) with the mini-stopband of the fundamental mode about the normalized frequency $u = a/\lambda = 0.26$ with $\epsilon = 11.56$ for the matrix and air filling factor $f = 37\%$. 1–4, extrema of interest.

layers. Their in-plane photoluminescence is collected through the cleaved edge after propagation either in unpatterned areas or through a photonic crystal waveguide [Fig. 1(a)]. The waveguide [W3, Fig. 1(b)] is defined by three missing rows along the ΓK direction of the photonic crystal array. The specific band edges that we used here are on the band-structure diagram $\omega(k)$ of Fig. 1(b) inside the photonic gap of the surrounding crystal. We work around the so-called mini-stopband of the W3 waveguide. This anticrossing is opened through Bragg diffraction between the fundamental and 5th-order guided modes.

Figure 1(a) shows the geometry used to probe the fundamental mode transmission in the W3 waveguide. The raw spectrum is shown in Fig. 2, along with the smoothed source spectrum.¹⁷ The emission of quantum dots inside the waveguide is probed as follows: we excite the luminescence of quantum dots in the waveguide, at approximately 10 μm from its output. For the propagating waveguide modes we are thus in the opened-resonator regime.¹⁸ Figure 2 shows the raw spectrum collected on the cleaved edge, and Fig. 3(b) shows the ratio at the source spectrum. A large peak and smaller peaks on the sides of the mini-stopband clearly appear. Their exact strength does not depend on excitation and collection conditions for a given setup, from a careful check. Optical amplification is ruled out by variable pumping data and from the diffraction-limited pumped area. The best peak-to-background ratio is in excess of 7. Similar peaks were observed for W3 waveguides of different lengths and for different excitation positions along the waveguide as long as we stayed in the opened resonator regime for propagating modes.

We interpret these data as being due to the enhanced 1D photon DOS of the photonic crystal waveguide at the mini-stopband edges. This DOS is deduced from the dispersion relation, including propagation losses. The losses of the different modes are precisely known from measurements.^{19,20} These values agree with the model whereby a fictitious imaginary dielectric constant in the airholes depicts propagation losses.²¹ The dispersion relation of Fig. 1(b) is calculated by use of a two-dimensional plane-wave expansion²² with the following parameters: $\epsilon_{\text{GaAs}}=11.56$, $\epsilon_{\text{holes}}=1+0.05i$, and an air filling factor of the photonic crystal array of $f=37\%$. A complex frequency is obtained: $\tilde{\omega}(k)=\omega'(k)+i\omega''(k)$, where $\omega'(k)$ is the standard dispersion relation of Fig. 1(b). Having such a physically correct value means that we can produce the proper smoothing of the 1D photon DOS

Fig. 2. Raw spectra from the three configurations of Fig. 1(a). The reference has been multiplied by 0.15 and smoothed for clarity.

Fig. 3. (a) Calculated 1D DOS of the photonic wire with the data of Fig. 1(b) used for the real part of the dispersion relation and the imaginary part of the same dispersion when $\epsilon_{\text{holes}}=1+0.05i$ in the airholes. (b) Modified DOS, with the modal filter, superimposed by the experimental normalized spectrum of emission from the waveguide.

singularity at band edges, without any adjustable parameter. With losses taken into account, the 1D DOS is simply the sum of Lorentzians, $\sim 1/[\omega - \tilde{\omega}(k)]^2$ for each k value of Fig. 1(b), with a fine enough k mesh [Fig. 3(a)]. It has four features, associated with extrema 1–4 of Fig. 1(b). This DOS is only the part of the photon DOS related to TE-polarized in-plane photon states. To account for the experimentally observed results, we ignore the nonresonant mode continuum of the slab claddings, as no light is collected there: our setup collects a small internal angle of $\pm 7^\circ$ about the normal, which contains chiefly guided modes of the photonic crystal waveguide.²⁰ Nor is it required to specify a local DOS, as the quantum dots are excited across several waveguide unit cells (each $0.25 \mu\text{m} \times 0.8 \mu\text{m}$), overlapping $\sim 90\%$ of the horizontal mode profile.

What is needed, however, is to take propagation from the emission spot to the outside collected modes into account, an issue also met to some extent in photonic crystal–opal related studies⁹ (for opals with infiltrated emitters, however, the local density of states is crucial, unlike here). Extrema 1 and 4 correspond to modes that have few chances of being detected: extremum 4 involves two coupled modes with odd symmetry, hence zero on-axis far field; extremum 1 involves a genuinely stationary mode, making unlikely a strong signal out of the lossy resonator.

The hybrid coupled modes about the mini-stopband suffer somewhat from being stationary as well, but, conversely, they also have a propagative component in the fundamental mode. We thus chose to modify the DOS by using a modal filter, mimicking the collection process as exactly as possible. A band-dependent coefficient $C(k)$ weights the value of the DOS of each mode. We choose it as the relative weight in Fourier space of on-axis plane waves in the plane-wave spectrum of the in-plane mode's magnetic field $H_k(\mathbf{r}) = \sum_{\mathbf{G}} h_{\mathbf{G}}(k) \exp[i(k + \mathbf{G})\mathbf{r}]$, that is, we privilege the presence of strong Fourier components for

plane waves that have zero transverse wave vector $G_{\perp}=0$. \mathbf{G} , the reciprocal wave vectors, and \mathbf{r} , the position vector, are two-dimensional, and $\{h_{\mathbf{G}}(k)\}$ is the eigenvector obtained when one is computing the dispersion relation of Fig. 1(b).²² The important point is that singularity 2 of the in-plane DOS is preserved, while contributions of singularities 3 and 4, while they are measurable, cannot be clearly distinguished [Fig. 3(b)].

This modification convincingly establishes that the observed peaks arise from the 1D DOS singularities of the photonic-crystal-type wire.²³ The W3 waveguide provides a clear signature at well-defined spectral locations, with a large signal stemming from the proper area of the system. The role of the detection process is reduced to as simple physics as possible. Data from broader waveguides exhibit similar peaks at edges of their mini-stopbands.

In conclusion, the spontaneous emission singularity in the power spectrum expected in a one-dimensional photonic system has been evidenced by the photoluminescence of quantum dots in a GaAs-based photonic crystal waveguide. Full knowledge of the modes in a two-dimensional picture, and an account of the collection process in a modal filter spirit, have provided a safe basis for this claim.
